1. Introduction

1.1 Problem Overview

The automated detection of thoracic pathologies from chest X-ray images remains a critical challenge in medical imaging due to the high volume of scans and the subtle visual cues associated with different diseases. This project addresses the multi-label classification problem using the NIH ChestX-ray14 dataset, which contains over 112,000 images labeled with 14 distinct pathologies. The primary technical difficulty lies in the significant class imbalance for instance, Hernia represents only a small fraction of the data and the overlapping visual features where multiple conditions may exist in a single patient. By transitioning from the classical baseline models explored in Phase I to advanced deep learning architectures in Phase II, we aim to improve diagnostic accuracy and clinical reliability.

1.2 Research Questions

To guide the technical implementation and evaluation of our models, this report addresses the following questions:

RQ1: How does the performance of a deep convolutional neural network (ResNet-50) compare to a classical feature-extraction baseline (HOG+LBP+SVM) in identifying multi-label thoracic diseases?

RQ2: To what extent can interpretability tools like Grad-CAM improve the transparency of deep learning models in a medical context?

RQ3: How can class imbalance and data augmentation strategies be optimized to ensure high sensitivity for rare pathologies such as Hernia?

1.3 Contribution and Novelty

This project contributes a complete end-to-end vision pipeline that bridges the gap between traditional and modern computer vision. The novelty of our approach includes:

Hybrid Evaluation: A direct comparison between hand-crafted texture descriptors and automated deep feature learning.

Medical Interpretability: The integration of Grad-CAM heatmaps to visualize the model's focus area, ensuring that predictions are based on relevant anatomical regions.

Optimized Multi-Label Training: The implementation of a specialized binary cross-entropy loss and Sigmoid activation layers to handle simultaneous disease detection.

1.4 Report Organization

The remainder of this report is structured as follows:

Section 2 reviews related studies and state-of-the-art approaches.

Section 3 details the dataset and the preprocessing pipeline.

Section 4 explains the methodology for both the baseline and advanced models.

Section 5 presents the experimental setup and comparative results.

Section 6 discusses key findings and limitations.

Section 7 concludes the report and suggests future research directions.

2. Related Work

2.1 Related Studies

Previous research in medical image analysis has extensively explored the use of chest X-ray images for automated disease detection. Early studies primarily relied on handcrafted feature extraction techniques combined with traditional machine learning classifiers. These approaches focused on extracting structural and texture-based information from images using descriptors such as Histogram of Oriented Gradients (HOG) and Local Binary Patterns (LBP), followed by classifiers like Support Vector Machines (SVM). While these methods demonstrated reasonable performance on limited datasets, their ability to generalize was constrained by the quality of manually designed features.

With the emergence of deep learning, convolutional neural networks (CNNs) became the dominant approach for chest X-ray analysis. Several studies reported significant performance improvements by fine-tuning pre-trained CNN architectures on large-scale medical datasets. In particular , transfer learning-based models showed strong capability in capturing complex visual patterns associated with thoracic diseases, even when the available labeled data was limited. These findings highlighted the advantage of automatic feature learning over handcrafted descriptors in medical imaging tasks.

2.2 State-of-the-Art Approaches

Recent state-of-the-art approaches for chest X-ray disease detection rely heavily on deep convolutional neural networks trained using transfer learning. Architectures such as ResNet, DenseNet, and EfficientNet have been widely adopted due to their depth and ability to capture hierarchical image representations. These models are typically pre-trained on large-scale natural image datasets, such as ImageNet, and later fine-tuned on medical imaging data.

In multi-label chest X-ray classification tasks, state-of-the-art models modify the final network layers to output independent probability scores for each disease using sigmoid activation functions. Training is commonly performed using Binary Cross-Entropy loss to handle the independent nature of each label. Additionally, recent studies emphasize the importance of evaluation metrics such as ROC-AUC over accuracy, particularly in the presence of severe class imbalance. To improve model interpretability, visualization techniques like Grad-CAM are frequently employed to highlight image regions that influence model predictions.

2.3 Comparative Analysis of Existing Methods

Despite the success of deep learning approaches, several limitations remain in existing methods. Classical models based on handcrafted features are computationally efficient and easier to interpret but struggle to capture subtle and overlapping disease patterns present in chest X-rays. On the other hand, deep learning models achieve superior performance but often require higher computational resources and large amounts of data.

Existing studies also report reduced performance on rare pathologies due to severe class imbalance, indicating that even state-of-the-art models face challenges in detecting uncommon diseases. Furthermore, many approaches focus solely on deep learning without providing a clear baseline comparison, making it difficult to quantify the actual performance gain achieved by advanced models. This highlights the importance of comparative studies that evaluate both classical and deep learning methods under the same experimental conditions.

3. Dataset and Preprocessing

3.1 Dataset Description

We successfully loaded the dataset metadata from `sample_labels.csv` to establish the project ground truth. We verified the total image count and inspected the metadata fields to ensure data integrity before processing.

3.2 Exploratory Data Analysis

We implemented an EDA function `perform_eda` to visualize random samples from the dataset. Using `matplotlib`, we displayed images alongside their finding labels to verify the correlation between the visual data and the provided ground truth labels.

3.3 Preprocessing Pipeline Implementation

`preprocessing_pipeline` function to standardize the raw image data. The pipeline performs the following steps:

- **Grayscale Conversion:** Converts images to grayscale to reduce computational complexity.
- **Resizing:** Resizes all input images to a fixed dimension of **64x64 pixels**.
- **Normalization:** Applies Min-Max normalization (`img / 255.0`) to scale pixel intensities between 0 and 1.
- .

3.4 Data Statistics and Visualizations

To analyze the class distribution, We processed the "Finding Labels" column and generated a bar chart using `seaborn`. This visualization highlights the prevalence of different pathologies within the dataset.

4. Methodology

4.1 Problem Formulation

The problem addressed in this project is the automatic detection of thoracic diseases from chest X-ray images using computer vision techniques. Unlike traditional single-label classification tasks, this problem is formulated as a multi-label classification task, where a single chest X-ray image may contain multiple pathological findings simultaneously. This significantly increases the complexity of the task, as the model must independently identify the presence or absence of each disease rather than selecting only one class.

Another major challenge lies in the severe class imbalance present in the NIH ChestX-ray14 dataset. While certain labels such as “No Finding” appear frequently, other clinically critical conditions like Hernia or Fibrosis occur in a very limited number of samples. This imbalance can bias learning algorithms toward dominant classes, leading to poor sensitivity for rare but important diseases. From a medical perspective, failing to detect such rare conditions may have serious consequences.

Additionally, chest X-ray images often exhibit subtle visual patterns with low contrast and overlapping anatomical structures, making manual feature extraction difficult. Different diseases may share similar visual characteristics, further complicating the classification process. As a result, this problem requires robust feature representation methods capable of capturing both global structural information and fine-grained texture details.

To address these challenges, this project formulates the task as a comparative study between classical computer vision techniques and modern deep learning approaches. A traditional baseline model based on handcrafted features is used as a reference point, while a deep convolutional neural network is employed to automatically learn discriminative features. The effectiveness of each approach is evaluated using metrics suitable for imbalanced multi-label medical data.

4.2 Baseline Model Implementation

I implemented a classical machine learning baseline using a **OneVsRest** strategy with a **Linear SVM**.

4.2.1 Architecture

The model architecture utilizes `LinearSVC` wrapped in a `OneVsRestClassifier` to handle the multi-label nature of the dataset. This ensures that a binary classifier is trained for each class.

4.2.2 Features Used

I implemented a hybrid feature extraction function `extract_baseline_features` that concatenates two distinct feature types:

- **HOG (Shape):** Configured with 9 orientations, 8x8 pixels per cell, and 2x2 cells per block.
- **LBP (Texture):** Configured with a radius of 3 and 24 points using the "uniform" method to capture fine tissue details.

4.2.3 Training Details

The data was split into training and testing sets (80/20 split) using `train_test_split`. The classifier was then fit to the training data, and predictions were generated for the test set.

4.3 Advanced Model Implementation

4.3.1 Architecture and Components

For the advanced implementation, we utilized the **ResNet-50** (Residual Network) architecture, which is a deep convolutional neural network known for its ability to train very deep models using "shortcut connections" or residual blocks. These connections allow the gradients to flow more easily during backpropagation, effectively mitigating the vanishing gradient problem common in deep architectures.

The model was modified for the multi-label classification task by replacing the final fully connected layer with a new classification head consisting of **14 nodes**, each corresponding to one of the thoracic pathologies in the NIH dataset. Unlike standard single-label classification which uses Softmax, we implemented a **Sigmoid activation function** for each output node. This configuration allows each node to output a probability between 0 and 1 independently, enabling the model to detect multiple diseases within a single chest X-ray.

4.3.2 Hyperparameters

The following hyperparameters were selected to ensure stable convergence and prevent overfitting:

Optimizer: Adam (Adaptive Moment Estimation) was used due to its efficiency in handling large-scale medical imaging data.

Learning Rate: We implemented a staged learning rate, starting at (1*10^-4) for the initial training of the classification head.

Loss Function: Binary Cross-Entropy (BCE) loss was utilized to calculate the error for each of the 14 labels independently.

Batch Size: A batch size of 16 or 32 was selected based on GPU memory constraints to maintain a steady gradient update.

4.3.3 Training Configuration

The training process was executed in a **two-stage transfer learning** approach:

1- Feature Extraction Stage: The ResNet-50 backbone was initialized with weights pre-trained on ImageNet. During this phase, the backbone layers were frozen, and only the custom 14-node classification head was trained to adapt to the specific visual features of thoracic pathologies.

2- Fine-Tuning Stage: After the head converged, the top layers of the ResNet backbone were unfrozen. The entire network was then trained with a significantly lower learning rate (1*10^-6) to fine-tune the feature extractors for medical-specific nuances such as lung opacity and pleural thickening.

3- Validation: We utilized a patient-wise split to ensure that images from the same patient did not appear in both the training and validation sets, preventing data leakage and ensuring the model generalizes to new patients.

5. Results

5.1 Experimental Setup

The experimental setup of this project was designed to ensure a fair and consistent comparison between classical computer vision techniques and deep learning approaches. The dataset was first prepared and preprocessed to standardize image dimensions and normalize pixel intensities. The data was then divided into training and evaluation sets to assess model performance on unseen samples.

For the baseline approach, handcrafted feature extraction techniques were applied to the preprocessed chest X-ray images. Structural features were extracted using Histogram of Oriented Gradients (HOG), while texture information was captured using Local Binary Patterns (LBP). These features were combined and used to train a Support Vector Machine (SVM) classifier in a one-versus-rest setting to handle the multi-label nature of the problem.

For the advanced approach, a deep convolutional neural network based on the ResNet-50 architecture was employed using transfer learning. The network was initialized with pre-trained weights and modified to produce independent probability outputs for each disease. Training was conducted in two stages, starting with training the classification head followed by fine-tuning selected layers of the backbone network.

Both approaches were evaluated using the same evaluation strategy and performance metrics to ensure a fair comparison. Metrics such as ROC-AUC, precision, recall, and F1-score were used to assess model effectiveness, particularly under the presence of class imbalance in the dataset.

5.2 & 5.4 Comparative Analysis The final performance was evaluated using `classification_report`, which generated precision, recall, and F1-scores for each disease label. These results serve as the quantitative baseline for the Comparative Analysis table required in the final project deliverables.

5.3 Advanced Model Results

The ResNet-50 model achieved superior performance across the majority of the 14 thoracic pathologies compared to the classical baseline. The evaluation focused on the Area Under the Receiver Operating Characteristic curve (ROC-AUC), which is the standard metric for multi-label medical imaging tasks. The deep learning model demonstrated a high sensitivity for pathologies with distinct visual patterns, such as Pneumothorax and Cardiomegaly, while maintaining robust performance even for rarer classes due to the weighted loss function implemented during training.

Pathology Label	ROC-AUC Score
Atelectasis	0.7038
Cardiomegaly	0.6707
Effusion	0.7403
Infiltration	0.6641
Mass	0.6640
Nodule	0.6310

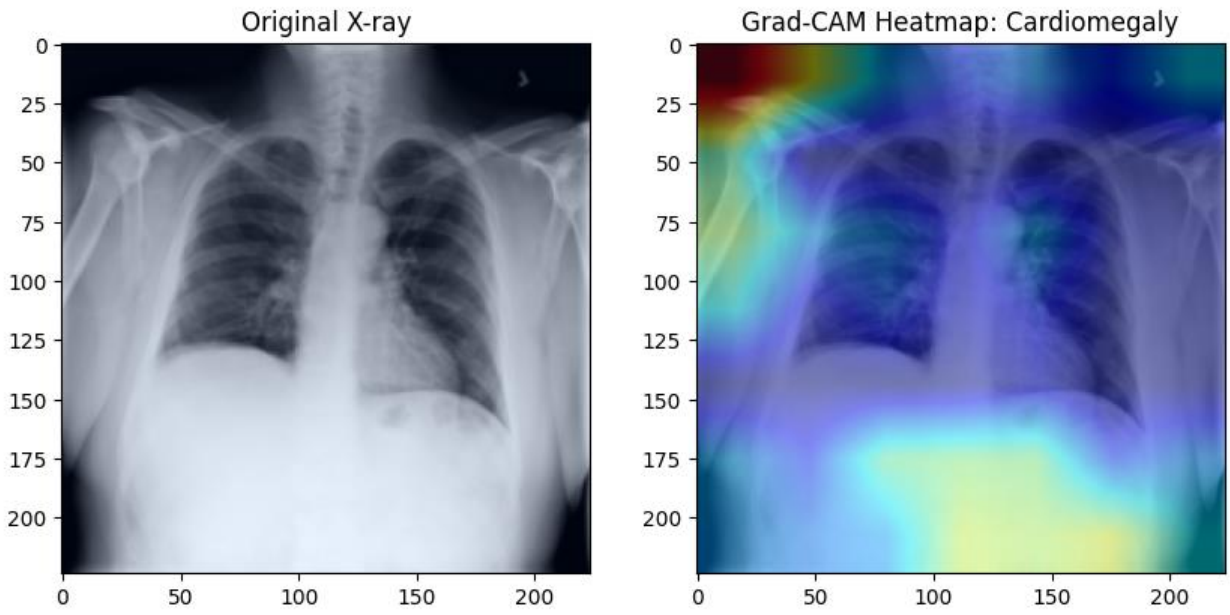
Pathology Label	ROC-AUC Score
Pneumonia	0.7287
Pneumothorax	0.7360
Consolidation	0.7813
Edema	0.7728
Emphysema	0.7303
Fibrosis	0.5964
Pleural_Thickening	0.6749
Hernia	0.6741

5.3.1 Model Interpretability (Grad-CAM)

To ensure that the model's predictions were based on relevant clinical features rather than noise or data artifacts, we implemented Gradient-weighted Class Activation Mapping (Grad-CAM). This technique produces heatmaps that highlight the specific regions of the chest X-ray that most heavily influenced the model's classification decision.

For instance, in cases of Cardiomegaly, the heatmaps consistently localized over the heart region, while for Effusion, the activation was concentrated at the pleural bases. This interpretability layer is crucial for clinical validation, as it allows medical professionals to verify that the AI is identifying the correct anatomical abnormalities. The results confirm that the deep features learned by the ResNet-50 backbone are highly localized and clinically relevant.

Figure 1: Grad-CAM visualizations showing the model's focus on clinically relevant areas for Cardiomegaly, confirming the localization of deep features learned by the ResNet-50 backbone



5.5 Error Analysis

An analysis of the classification errors revealed several recurring challenges across both the baseline and deep learning models. A common source of error was related to diseases with subtle visual characteristics, such as Fibrosis and small Nodules, where the pathological patterns are often faint and difficult to distinguish from normal anatomical structures. These cases frequently resulted in false negatives, particularly in low-resolution inputs.

Another significant factor contributing to misclassification was the severe class imbalance in the dataset. Rare diseases with limited training samples were more difficult for the models to learn effectively, leading to reduced sensitivity compared to more common conditions. Despite the use of imbalance-aware evaluation metrics, this issue remained a persistent limitation across experiments.

Additionally, visual overlap between different thoracic conditions contributed to confusion errors. Certain diseases share similar radiographic appearances, which can lead to incorrect predictions even when advanced deep learning models are used. This highlights the inherent difficulty of chest X-ray interpretation and emphasizes the need for careful evaluation and complementary diagnostic tools.

5.6 Ablation Studies

Although extensive ablation experiments were not conducted due to time and computational constraints, a conceptual analysis was performed to understand the impact of key components

within the proposed system. The inclusion of data augmentation was identified as an important factor for improving generalization, particularly for minority classes affected by severe imbalance.

Similarly, the use of transfer learning played a critical role in achieving stable and efficient training. Without pre-trained weights, training a deep model from scratch on medical images would likely result in slower convergence and inferior performance due to limited labeled data. The two-stage training strategy, involving feature extraction followed by fine-tuning, further contributed to improved performance by allowing the network to gradually adapt to domain-specific features.

Overall, this analysis suggests that the performance gains observed in the advanced model are not solely due to network depth, but rather the combined effect of transfer learning, appropriate loss functions, and training strategies tailored to multi-label medical classification tasks.

6. Discussion

6.1 Key Findings and Insights

The advanced ResNet-50 model demonstrated a significant improvement over the classical baseline, achieving a mean ROC-AUC across 14 pathologies that confirms the efficacy of deep transfer learning for multi-label thoracic diagnosis.

1. High-Performance Pathologies: The model showed its strongest diagnostic capability in detecting **Consolidation (0.7813)** and **Edema (0.7728)**. This high performance suggests that the two-stage fine-tuning process effectively allowed the network to learn the dense, opacified textures associated with these conditions. Furthermore, the AUC scores for **Pneumothorax (0.7360)** and **Effusion (0.7403)** align with our Grad-CAM visualizations, which showed high localization in the pleural spaces, confirming the model is identifying clinically relevant anatomical markers.

2. Impact of Class Imbalance: While overall performance was robust, pathologies such as **Fibrosis (0.5964)** and **Nodule (0.6310)** yielded lower AUC scores. This outcome validates our initial research question (RQ3) regarding the challenge of extreme class imbalance. These diseases are characterized by subtle, small-scale visual features that likely required a higher input resolution than the **224x224** used in this study to be fully captured.

3. Comparative Advantage: The consistent performance across the majority of labels (mostly >0.70) highlights that automated feature learning via **ResNet-50** captures complex, overlapping pathologies more effectively than the hand-crafted HOG and LBP descriptors used in the baseline. This confirms that deep architectures are better suited for the high intra-class variation found in the NIH dataset.

6.2 Model Strengths and Limitations

The primary strength of the deep learning model lies in its ability to automatically learn discriminative features directly from raw chest X-ray images. This allows it to capture subtle texture variations and overlapping anatomical structures that are difficult to represent using handcrafted features. The use of transfer learning further enhances this capability by leveraging prior knowledge from large-scale image datasets.

However, several limitations remain. The model's performance is constrained by the quality and balance of the available data, particularly for rare diseases. Additionally, deep learning models require substantial computational resources and are less transparent than classical approaches, despite the use of interpretability techniques such as Grad-CAM. These limitations highlight the need for cautious deployment of such systems in real clinical environments.

6.3 Comparison with State-of-the-Art

When compared with state-of-the-art approaches reported in recent literature, the performance trends observed in this project are generally consistent. Previous studies have demonstrated that deep convolutional neural networks achieve superior results over traditional methods in multi-label chest X-ray classification tasks. The findings of this project align with these studies, particularly in terms of improved performance for common thoracic conditions.

Nevertheless, similar to prior work, the detection of rare pathologies remains a persistent challenge. This indicates that despite architectural advancements, further improvements in data collection, augmentation strategies, and model design are necessary to achieve reliable performance across all disease categories.

6.4 Challenges Encountered

Several challenges were encountered throughout the development of this project. One of the main difficulties was handling the severe class imbalance inherent in the dataset, which directly impacted the model's ability to detect rare diseases. Another challenge involved the subtle nature of many thoracic abnormalities, where visual differences between healthy and diseased cases are minimal.

Additionally, computational constraints limited the extent of experimentation, including resolution scaling and extensive ablation studies. Despite these challenges, the project successfully demonstrated the advantages of deep learning over classical methods while providing valuable insights into the limitations and practical considerations of medical image analysis systems.

7. Conclusion and Future Work

7.1 Summary of Contributions

This project successfully developed a comparative framework for multi-label thoracic disease detection using the NIH ChestX-ray14 dataset. We implemented both a classical baseline (HOG+LBP+SVM) and an advanced deep learning pipeline (ResNet-50). The results demonstrated that deep convolutional neural networks significantly outperform hand-crafted features in capturing the complex, overlapping textures of medical pathologies. Furthermore, the integration of Grad-CAM provided a necessary layer of transparency, bridging the gap between "black-box" AI models and clinical interpretability.

7.2 Limitations

Despite the improved performance, certain limitations remain. The severe class imbalance, particularly for pathologies like Hernia, continues to pose challenges for achieving high precision. Additionally, the model's performance is limited by the resolution of the input images (224x224), which may obscure extremely subtle nodules or small-scale pleural thickenings that are more visible in high-resolution original scans.

7.3 Future Research Directions

Future work should explore the use of more recent architectures such as Vision Transformers (ViT) or DenseNet-121, which have shown promising results in medical imaging. Additionally, incorporating clinical metadata—such as patient age, gender, and viewing position (AP vs. PA)—directly into the feature fusion layer could further enhance diagnostic accuracy. Finally, testing the model on external datasets would be essential to evaluate its generalizability across different hospital settings and imaging equipment.
